Abstract

Understanding the spatio-temporal elimination pattern of grazing cattle is important for grazing management. We thus developed a new method of detecting defecation events using a three-axis accelerometer. The accelerometer was fixed on the tails of three Japanese Black steers in a pasture, with the *x*-, *y*-, and *z*-axes being set to the front-to-back, side-to-side, and vertical directions relative to the normal tail position, respectively. The defecation behavior was also visually observed. The 3-sec moving average was calculated from raw acceleration data and charted along the time course. The *x*-axis and *z*-axis accelerations showed convex upward and downward curves, respectively, at the defecation events. By using the synchronous signs of both curves, we could visually detect virtually all defecation events. And in order to detect defecation events automatically, we created six variables (i.e., maximum, minimum, and area in convex curve per 30 sec for *x*- and *z*- axes) and applied quadratic discriminant analysis (QDA) and a support vector machine (SVM). The critical success index values in QDA and the SVM were 0.8 and 0.98, respectively, using the leave-one-out cross-validation method. We concluded that the use of an accelerometer on a steer's tail is effective in visually and statistically detecting defecation events.

Introduction

Excreta are a major nutrient source for plants in a grazing system (During and McNaught 1961; During and Weeda 1973). Potassium and phosphorus are excreted mainly in urine and feces, respectively, and nitrogen is excreted in significant proportions in both feces and urine (Haynes and Williams 1993). However, a certain percentage of grazing animals' excreta is eliminated on inaccessible or undesirable sites such as resting and watering places (Nakamura and Fukukawa 1973; Hirata et al. 2009; Auerswald et al. 2010), and the nutrients in that excreta cannot be reused on grazing land (Parfitt 1980; Selbie et al. 2015). To increase the circulation of such nutrients in a grazing system, a grazing layout and schedule are needed based on an understanding of the spatio-temporal elimination pattern of the grazing animals.

To date, most studies on the elimination behavior of domestic animals have been conducted by behavioral

observation (e.g., Orr et al. 2012) or by simply counting the number of fresh dung pads or urine patches per area (e.g., MacLusky 1960; Moir et al. 2011). Although these methods are reasonably reliable for measuring the excreta distribution in pastures, they are rather labor-intensive and thus such research has been limited to short-term periods and/or small areas. In addition, difficult conditions such as darkness, observation from a distance, and observer fatigue may cause underestimations of the elimination behavior and excreta distribution.

A new system is thus needed to monitor elimination behavior as a replacement for such labor-intensive methods. Betteridge et al. (2010) developed an automatic recording system for urination events during the grazing period that uses a thermistor suspended below the animal's vulva to detect a rise in temperature at urination. Moreover, an automatic defecation recording system must also be developed to determine the actual situation of animal excreta in a grazing system.

Following advances in micro-electromechanical systems technologies, animal behavior studies using a miniaturized accelerometer have undergone rapid development. Animal-attached accelerometers measure changes in the velocity of the body over time and can quantify fine-scale movements and body postures unlimited by visibility, observer bias, or the scale of space use (Brown et al. 2013). Ueda et al. (2011) and Yoshitoshi et al. (2013) fitted an accelerometry-based activity monitor on the neck of cattle and succeeded in distinguishing foraging activity from other activities. Watanabe et al. (2008) and Giovanetti et al. (2017a) measured under-jaw accelerations of cattle on a three-axis accelerometer, and discriminated eating, ruminating, and resting activities in a grazed pasture. De Passillé et al. (2010) and Ledgerwood et al. (2010) fitted a three-axis accelerometer on the leg and classified the gait patterns (galloping, trotting, and walking) of calves and the lying/standing behaviors of dairy cows, respectively. Fukasawa et al. (2018) measured the sleeping posture of cattle in lying positions by fitting a three-axis accelerometer on a halter on the middle occipital region. Mansbridge et al. (2018) and Barwick et al. (2018) classified the eating behaviors in sheep using a three-axis accelerometer worn on the ear. The findings above clearly show that an accelerometer is a powerful tool for distinguishing animal behaviors.

However, few studies have used an accelerometer to investigate the excretion behavior of livestock. Bueno et al. (1981) successfully determined the urination and defecation events of cows by recording the tail position using a chart recorder connected to an FM receiver that obtained signals from an FM transmitter fixed on the cow's back. A cow first raises her tail before defecating or urinating. In contrast, a steer raises his tail only before defecating (Brownlee 1950; Albright and Arave 1997; Aland et al. 2002). We hypothesized that an accelerometer fixed on a steer's tail could more easily and precisely record the tail movements, and thus detect the tail-raise movement prior to defecation. In the present study, we explored the potential for detecting defecation events by recording the acceleration of steers' tail movements in a grazed pasture.

Materials and methods

1. Animals and study site

The study was conducted in 2011 on three Japanese Black steers stocked in a pasture (8.1 ha) with seven Japanese Black cows and their calves. The ages and body weights of the steers in May 2011 were as follows: Steer 1, 37 months old and 604 kg; Steer 2, 37 months old and 652 kg; and Steer 3, 12 months old and 278 kg. The

stocked pasture was located at the Hokkaido Agricultural Research Center, National Agriculture and Food Research Organization (HARC/NARO) (42°59'N, 141°24'E), Sapporo, Japan, and consisted of a relatively flat section (3.1 ha, average slopes of 2.1°) and a sloped section (5.0 ha, 8.6°). The three steers, seven cows, and calves could move freely in both sections of the pasture during the stocking period from May to October 2011.

2. Detection of defecation behavior using an accelerometer

We used an accelerometer (Hitachi AirSense™ Entry Model 02 Plus, Hitachi WirelessInfo, Tokyo; 43 × 35 × 15 mm, weighing 40 g) equipped with an orthogonal three-axis acceleration sensor ranging from -2 G to 2 G, and a data logger that could record data at 0.05-sec intervals for 14 days. The acceleration sensor recorded accelerations related to changes in movements (dynamic accelerations) and static acceleration (gravity). The accelerometer was wrapped in a vinyl bag for waterproofing and fixed on the upper part of the tail (approx. 12-24 cm below the anus) of each steer by an elastic adhesive bandage (ELATEX 4, Alcare, Tokyo) (Fig. 1).

The *x*-, *y*-, and *z*-axes of the fixed accelerometer were set to longitudinal (front-to-back), horizontal (side-to-side), and vertical directions relative to the normal tail position, respectively. In the normal position, the tail simply hangs naturally straight downward. The tail position is generally maintained in walking, grazing, feeding, and idling activities (Albright and Arave 1997). When a steer defecates, its tail is always raised. A 3- to 4-hr visual observation of behavior was conducted nine times in September and October 2011 during a variety of activity periods, such as grazing and resting periods. For each observation, one observer recorded the activities of the steers at 1-min intervals and the time of defecation events, unless they were at a distant place.

3. Preprocessing of acceleration data

We calculated the 3-sec moving average of raw acceleration data on the *x*- and *z*-axes to smooth the fluctuations, and charted the changes over 4-min sets of moving averages using Excel 2007 Visual Basic for applications (Microsoft, Tokyo). The *y*-axis data (lateral tail movements) were not analyzed in this study because it was thought that the *y*-axis data would not be involved in the tail-raise movement.

On the 3-sec moving average chart, we checked whether the defecation events identified by actual observation could be detected from the acceleration waveform.

To automatically detect the steers' defecation

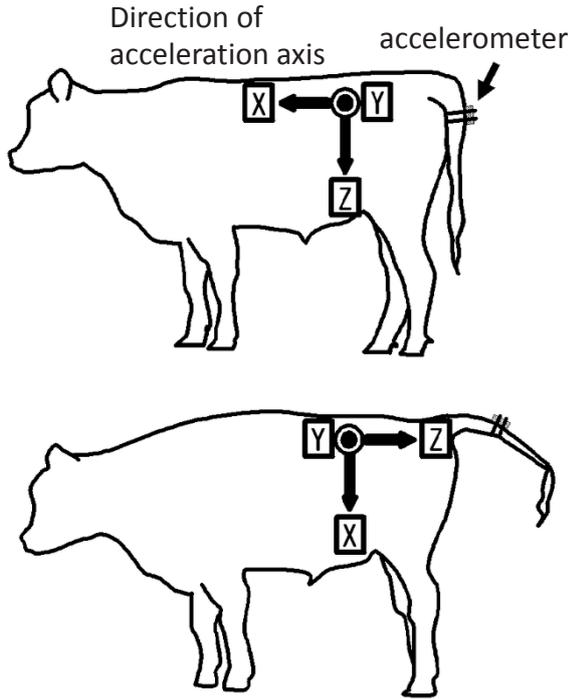

Fig. 1. The accelerometer attached to a steer's tail

In the normal standing posture, where the tail simply hangs naturally straight downward, the x -, y -, and z -axes of the accelerometer indicate the longitudinal (front-to-back), horizontal (side-to-side), and vertical body axes, respectively (*upper illustration*). During defecation, the x -, y -, and z -axes change directions close to the vertical, side-to-side, and front-to-back body axes, respectively (*lower illustration*).

events, we created the following six variables from the 3-sec moving average of the acceleration data in a 30-sec moving window: the maximum, minimum, and area between the moving average data and minimum in the x -axis (or maximum in z -axis) per 30 sec for the x - and z -axes, respectively.

$$\max x_i = \max \{x_{i+t} \mid t = 0, 1, 2, \dots, 30\}$$

$$\max z_i = \max \{z_{i+t} \mid t = 0, 1, 2, \dots, 30\}$$

$$\min x_i = \min \{x_{i+t} \mid t = 0, 1, 2, \dots, 30\}$$

$$\min z_i = \min \{z_{i+t} \mid t = 0, 1, 2, \dots, 30\}$$

$$\text{area } x_i = \frac{1}{2} \sum_{t=1}^{30} [(x_{i+t} - \min x_i) + (x_{i+t-1} - \min x_i)]$$

$$\text{area } z_i = \frac{1}{2} \sum_{t=1}^{30} [(\max z_i - z_{i+t}) + (\max z_i - z_{i+t-1})]$$

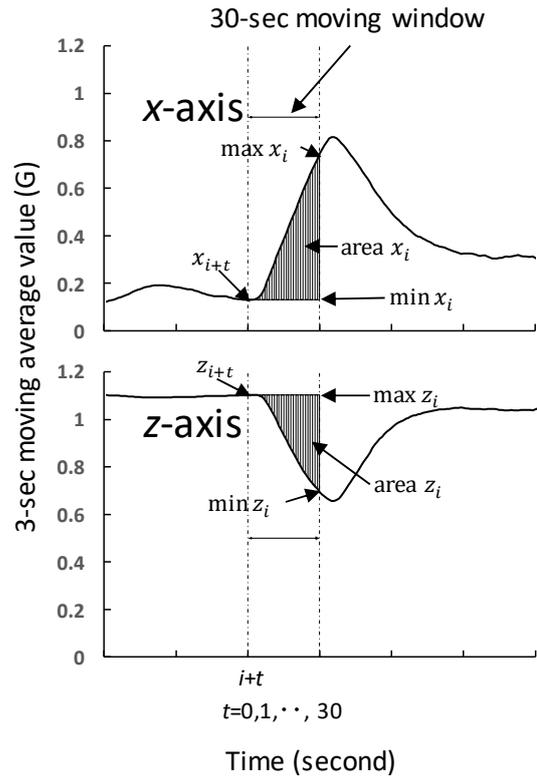

Fig. 2. An example of creation of the variables (max, min, area) to detect defecation events

Let x_{i+t} and z_{i+t} be the 3-sec moving average values for the x - and z -axes at the time $i+t$, respectively. A 30-sec moving window is made in the range from $t = 0$ sec (i.e., i) to 30 sec (i.e., $i+30$) at the time i . The maximum and minimum values in the window are regarded as $\max x_i$ and $\min x_i$ in the *upper figure* and $\max z_i$ and $\min z_i$ in the *lower figure*. Area x_i is calculated as the sum of 30 trapezoidal areas with the difference between x_{i+t} and $\min x_i$ as the upper base, the difference between x_{i+t-1} and $\min x_i$ as the lower base, and 1 sec as the height, under the conditions: $1 \leq t \leq 30$. Area z_i is calculated as the sum of 30 trapezoidal areas with the difference between z_{i+t} and $\max z_i$ as the upper base, the difference between z_{i+t-1} and $\max z_i$ as the lower base, and 1 sec as the height, under the conditions: $1 \leq t \leq 30$.

where x_{i+t} and z_{i+t} are the 3-sec moving average values in the x - and z -axes, respectively, i is the second number of the acceleration recording, and t is the time in sec in a 30-sec moving window (i.e., 0-30) (Fig. 2). Area x_i is the sum of 30 trapezoidal areas calculated at 1-sec intervals, where the difference between x_{i+t} and $\min x_i$ is regarded as the upper base, the difference between x_{i+t-1} and $\min x_i$ as the lower base, and 1 sec as the height, under the conditions: $1 \leq t \leq 30$. Similarly, area z_i is the sum of 30 trapezoidal areas regarding the difference between z_{i+t} and $\max z_i$ as the upper base, the difference between z_{i+t-1} and

max z_i as the lower base, and 1 sec as the height, under the conditions: $1 \leq t \leq 30$. These six variables were calculated every sec. To create the subsequent dataset as defecation data, we sampled one dataset of the six variables every time the tail began to rise for defecation, based on behavior observation data. As non-defecation data, we also sampled one dataset every minute when no defecation events but only maintenance activities were observed. A dataset was created for each steer by combining the sampled data (defecation and non-defecation data).

4. Statistical analyses

A Welch test was applied to determine whether the difference in means between the two events (defecation and non-defecation) for each variable in the dataset is significant (Rasch et al. 2011, Natori 2014). We conducted quadratic discriminant analysis (QDA) and used a support vector machine (SVM) with a Gaussian Radial basis kernel function to classify both events for each steer and for all three steers. Discriminant analysis (DA) is an effective method of classifying animal activities (Giovanetti et al. 2017b, Decandia et al. 2018). In particular, QDA can be used without the assumption of homogeneity in the variance-covariance matrix between activities (events), although the assumption of a normal distribution in each activity is needed (Mizuta et al. 2005, Jin 2007). A kernel SVM is also a powerful method of classifying animal activities with a linear approach, using a kernel function that transforms a dataset with a nonlinear data structure into a linearly separable dataset in higher-dimensional feature space (Jin 2007, Martiskainen et al. 2009).

The developed models were validated by the leave-one-out cross-validation (CV) or leave-one-head-out CV method. In the leave-one-out CV method, the training model was created using all but one data on each steer or all three steers, and the model was validated using the excluded one as test data. The above method was repeated while assigning the test to all the data with replacement, and we compared the results obtained from the test data with the actual observed events. In the leave-one-head-out CV method, the model was created using the data on all the steers except one head, and the model was validated

using the excluded steer’s data (Tsenkova et al. 2009).

We evaluated the predictive accuracy obtained with QDA and the SVM by using the critical success index (CSI) values that range from 0 to 1, with 0 indicating no correct answer and 1 indicating all correct answers (Schaefer 1990). The CSI focuses on the forecasts of rare events, that is, the ratio of the number of true positives (correct event forecasts, hits) to the number of true positives + false positives (incorrect event forecasts, false alarms) + false negatives (missed events, misses). True negatives (correct no-event forecasts) are ignored in this index to overcome the problem of numerous correct no-event forecasts (i.e., common maintenance behaviors—grazing, ruminating, resting without defecating) that increase the correct forecast rate.

The creation of the acceleration variables, Welch test, and subsequent QDA and SVM with CV were performed using statistical software “R” ver. 3.4.3 (R Core Team 2017). In QDA and the SVM, we used the “qda” function in the package “MASS” and the “ksvm” function in the package “kernlab” in “R” with the “leave-one-out-cross-validation” argument or the “predict” function, respectively.

Results

1. Behavior observations of defecation events

Based on 72.3-hr observation, a total of 52 defecation events and their prior activities were recorded as listed in Table 1. The total numbers of observed defecation events for Steers 1, 2, and 3 were 18, 24, and 10, respectively. The activities observed just before the defecation events for all steers were grazing (29 times), standing from lying (11 times), walking (10 times), and resting (2 times).

2. Visual detection of defecation events using acceleration change charts

Figure 3 shows the 3-sec moving average values in the x - and z -axes in defecating and other activities. The x -axis values that indicate the front-back axial direction relative to the normal tail position showed a convex upward curve at the defecation events, whereas the z -axis

values that indicate the vertical axial direction relative to the normal position showed a convex downward curve at the defecation events (Fig. 3 (a)-(c)). In most cases, the two curves intersected, although the enclosed area between both curves varied (Fig. 3 (a), (b)). In a few cases, the two curves did not intersect (Fig. 3 (c)).

When the steer rose (from lying to standing), the x-axis acceleration rose steeply, like a convex upward curve (Fig. 3 (d)). But due to the lower acceleration values of the x-axis while the steer was lying down, the movement from lying to standing could be distinguished from the movement of a defecation event. Moreover, tail-raise movements were also observed during running or walking (Fig. 3 (e)). However, almost all of these activities were not confused with defecation events, based on an examination of such differences as the peak height and width (sharpness). The signs of the synchronous convex upward and downward curves on the acceleration charts could be used as markers to detect defecation events.

Figure 4 shows an example of a 3-hr period of acceleration changes on the tail. Here, three observed defecation events (at 10:17, 10:55, and 11:24) could be identified on the chart, although the defecation event at 10:17 just after standing was somewhat difficult to identify. Other tail movements were also observed on the charts, such as tapping movement of the tail while the steer was ruminating and lying down. However, due to the rapid acceleration changes (sharp peaks), those movements were never confused with defecation activities.

3. Statistical classification of defecation events using acceleration variables

In the observed defecation events, the means of the four acceleration variables (min x , max x , area x , and area z) were significantly higher than those in the non-defecation events; in contrast, the means of min z in the defecation events were significantly lower ($P < 0.01$, Table 2). There were no significant differences in the means of max z between the two events. In a comparison between the steers, the means of variables in Steer 1 were higher in min x , max x , and area z , and lower in min z than those in Steers 2 and 3.

Using the five variables (min x , max x , area x , area z and min z) with significant differences, we applied QDA and the SVM for each steer and for all three steers. In QDA followed by leave-one-out CV (i.e., use of the same steer in training model and test sets), the CSI values for Steers 1, 2, 3, and all steers were 0.82, 0.92, 0.9, and 0.8, respectively (Table 3). In contrast, in QDA followed by leave-one-head-out CV (i.e., use of the different steers in training model and test sets), the CSI values for Steers 1, 2, and 3 were 0.33, 0.83, and 0.91, respectively. The low

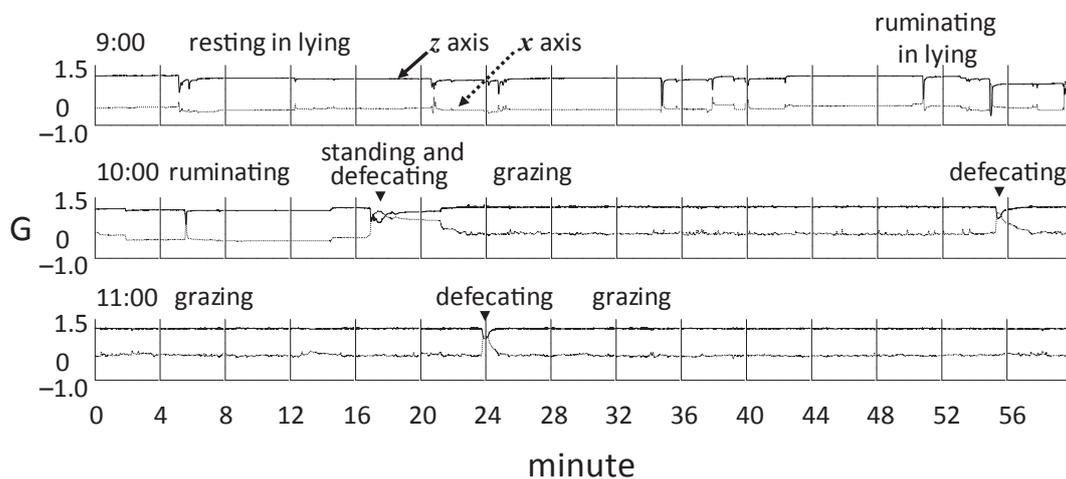

Fig. 4. An example of acceleration changes on the tail of Steer 2 over a 3-hr period on 5 October 2011, with behavioral observation

Three defecation events were observed at 10:17 (after standing), 10:55, and 11:24, the latter two of which occurred during grazing activity.

value for Steer 1 was due to many false alarms (FP). In the SVM followed by leave-one-out CV, the CSI values for Steers 1, 2, 3, and all steers were 0.95, 1, 1, and 0.98, respectively, which are higher than those in QDA. However, in the SVM followed by leave-one-head-out CV, the CSI values for Steers 1, 2, and 3 were 0, 0.13, and 0.3, respectively, which are lower than those in QDA. The low values were due to many misses (FN) in the detection of defecation events.

Discussion

1. Visual detection of defecation events on acceleration charts

Our present results confirmed that the use of an accelerometer on a steer's tail was effective in detecting

defecation events. Such tail-raise movements are also observed during activities other than eliminating, such as galloping, gamboling, bucking, sexual activity, and calving (Bueno et al. 1981; Albright and Arave 1997). However, in the present study, almost all of the defecating events could be distinguished from other tail-raise movements by using the characteristic acceleration change sign (i.e., occurrence of synchronous convex upward and downward curves).

We consider the following generalizations regarding this acceleration change sign. When the steer raises its tail to defecate, the *x*-axis of the accelerometer, which initially indicates the front-back direction of the steer, changes from the front-back direction to the oblique or vertical direction. Then, when the tail is lowered after the end of defecation, the *x*-axis direction returns to the front-

back direction. In the process of these directional changes, the static acceleration value of the x -axis rises to > 0.8 G (max x value) with upward tail movement, and then reverts to the initial state with downward tail movement. The increase and decrease in the static acceleration value make a convex upward curve with the dynamic movement of the tail.

In contrast, the static acceleration value of the z -axis, which initially indicates the vertical direction of the steer, falls from near 1 G (max z value) to 0.18-0.66 G (min z values) during upward tail movement and then is recovered during downward tail movement. Consequently, the acceleration changes of the z -axis show a convex downward curve for the defecation event. By these mechanisms, the synchronous convex upward and downward curves occur in defecating events. Conversely, in other tail-raise movements, the tail does not rise vertically from the normal position to the front-back (body-axis) direction (i.e., no simple movement of gravity acceleration between x - and z -axes). Moreover, the tail's up-and-down movement is more rapid than that in defecating, showing a sharp peak rather than a convex curve. For these reasons, we consider that the other tail-raise movements do not show the occurrence of synchronous convex upward and downward curves, and that the synchronous curves act as

markers only for eliminating events.

2. Statistical detection of defecation events

The statistical classification of defecation events by the SVM had higher CSI values than those by QDA in the leave-one-out CV method. The higher classification rate by the SVM is in agreement with other studies (Meyer et al. 2003, Garcia-Ruiz et al. 2013). QDA classifies data into two groups using a quadratic function in the dimensional plane determined by the number of input variables. In contrast, a kernel SVM creates an optimal higher-dimensional plane from the input variables, and in the plane, it determines the largest margin (the support vector), which linearly divides the data into two groups. With its creation of the higher-dimensional plane, the kernel SVM classifier allows for a better separation and classification of the data compared with other models (Garcia-Ruiz et al. 2013; Kurita).

However, in the leave-one-head-out CV method (in which the predicted steer's own data was not included in creating the training model), the CSI values obtained by the SVM were lower than those obtained by QDA, which might be due to the strong discrimination power of the SVM. The mean values of the variables used differed greatly between Steer 1 and Steers 2 or 3 (Table 2).

The difference between the steers significantly affected creation of the training model and resulted in low CSI values, especially for Steer 1. In general, there is a slight difference between individuals in the tail's up-and-down movement, and tail-up form in defecating events. In addition, in fixing an accelerometer on the tail, the location and angle of the device on the tail may differ slightly due to the difference in the shape (line) of the tail and the difficulty of fixing the device on the tail. Therefore, the differences between individuals and between fixation trials should be considered when creating a training model. The predicted individual's own data or the data from various individuals and fixation trials should be included in the training samples.

3. Future studies

In the present study, the statistical detection of defecation events of steers was successful with high accuracy. In the case of cows, however, there is still the problem of events being misinterpreted as urination activities. Cows are known to raise their tails not only for defecation but also for urination (Brownlee 1950). Thus, studies on the elimination activity of cows must discriminate between defecation and urination activities. In a trial using an accelerometer fixed on cows' tail, the acceleration pattern (synchronous convex upward and downward curves) in urination events was similar to that in defecation events, although the curve shape was slightly different (Watanabe et al., unpublished). In future studies, further development of the detection model is needed, including the discrimination between the defecation and urination of cows through detailed analyses of the shape of the acceleration curves.

Conclusion

We developed a new method of detecting steer defecation events that uses a three-axis accelerometer fixed on the tail, in which the *x*-axis and *z*-axis are set to the front-back and vertical directions relative to the normal tail position, respectively. In defecation events, the *x*-axis and *z*-axis accelerations showed convex upward and downward curves, respectively. By using the signs of the two synchronous curves on the acceleration chart, we were able to visually discriminate steer defecation events from other activities. In addition, the automatic classification of defecation events by QDA or the SVM succeeded with high CSI values. These results suggest that the tail-acceleration measurement method is effective in detecting defecation events and will contribute to studies of in-pasture nutrient cycling.

Acknowledgements

We wish to express our sincere appreciation to Ms. Shizue Nakajima of the HARC/NARO Daily Production Research Division for her assistance with the data analysis and field experiments, and to Mr. Kimiaki Ueda, Mr. Yukio Akazawa, and Mr. Mitsuharu Kato of the HARC/NARO Research Support Center for their assistance in the field experiments and cattle grazing management.
