

II. Farming Operation

1. Soil Pulverization and Germination of Uplnd Crops

Hitoshi TAKAHASHI
Vichien SASIPRAPA
Supachai BANGLIANG

It is extremely difficult to pulverize heavy clay soils of paddy fields well enough to ensure good germination of seeds when upland crops are grown in dry season. The following two experiments were undertaken to study proper land preparation for growing upland crops.

1) *Relationship between size of soil clods and germination of upland crops (1975)*

The experiment was conducted to obtain the fundamental information about the size of soil clods required for good germination of upland crops.

Materials and method

Wooden frames containing soil clods of different size were prepared for seed beds to examine the germination and initial growth of crops.

Treatment:

| | | |
|--------------------|---|-------------------|
| Test crops: | Sorghum (representing the crops of small size seed) | (S ₁) |
| | Maize (representing the crops of large size seed).. | (S ₂) |
| Size of clod: | < 2 cm | (C ₁) |
| | 2 — 3 cm | (C ₂) |
| | 3 — 4 cm | (C ₃) |
| | > 4 cm | (C ₄) |
| Depth of seeding: | 2 cm | (D ₁) |
| | 4 cm | (D ₂) |
| Irrigation method: | Irrigated from the bottom (similarly as furrow irrigation | (I ₁) |
| | Irrigated from the top (similarly as rainfall | (I ₂) |

Replication: 2 times

Size of wooden frame: 45 cm × 45 cm × D. 14 cm

Seeding: 24 March, 1975

Growth check of seedlings: 3 April, 1975

Results

The emergence and growth of seedlings are shown in Fig. 1-1 and 1-2; Table 1-1 shows the F value as the result of statistical analysis on those data.

The percentage of seedling emergence was high as soil clods were fine. Especially in case of small size seed such as sorghum, emergence was obviously depressed in the seed bed containing large clods. Fine clods of soil induced rapid and uniform emergence as

indicated by less average number of days for emergence and less number of days for 90% emergence of whole emerged seedlings.

2) *Effects of farming operation of preceding rice crop on efficiency of land preparation and growth of succeeding upland crops (1974 — 1975)*

The experiment was conducted to clarify the effect of farming operation in rice cultivation such as puddling and application of compost to soil, on the efficiency of land preparation and the growth of succeeding upland crops with reference to soil moisture conditions at tilling time.

Materials and method

Treatment:

| | | |
|---|------------------------|-------------------|
| Puddling for rice cultivation | { no puddling | (P ₁) |
| | { light puddling | (P ₂) |
| | { heavy puddling | (P ₃) |
| Compost application for rice cultivation | { 0 tons/ha | (C ₁) |
| | { 5 tons/ha | (C ₂) |
| | { 20 tons/ha | (C ₃) |
| Soil moisture content when the field was tilled for succeeding upland crops | { low | (M ₁) |
| | { moderate | (M ₂) |
| | { high | (M ₃) |

Layout: A split plot design was applied to dispose M treatment as a main plot, P and C treatments as sub-plots with one replication. The size of sub-plot was 11 m × 24 m = 264 m². L 27 (3¹³) table was employed for a statistical analysis.

Cultivation of rice:

Variety: RD 1

Transplanting: 24 July, 1974 (20 day seedling)

Fertilizer: N: 40 Kg/ha (1/2 for basal and 1/2 for top dressing)

P₂O₅: 25 kg/ha

K₂O: 12.5 kg/ha

Spacing: 25 cm × 25 cm

Harvesting: 11 November, 1974

Tilling: Tillings were made 3 times in each plot with a rotary tiller (Howard Rotavator) attached to a tractor (MF 178), at different dates varied according to soil moisture treatments as shown in Fig. 1-3.

Germination test: Wooden frames (45 cm × 45 cm × D. 14 cm) which were filled up with soils taken from each plot after tilling were prepared for seed beds. Maize seeds were sown on the beds with a rate of 50 seeds per frame on 13 February, 1975.

Cultivation of upland crops in the field: Nine crops such as maize, sorghum, rice, soybean, peanut, mungbean, cotton, sunflower and sesbania were seeded after third tilling, on December 19 in M₃ plot, February 11 in M₂ plot and March 17 in M₁ plot.

Results

1. Growth of rice.

As shown in Table 1-2 and 1-3, any effect of puddling and compost application was not observed on the growth and yield of rice. However, puddling obviously affected the emergence and development of weeds (Table 1-4). Weed population

was evidently abundant in non-puddling plot (P_1) comparing with that in puddled plots (P_2 and P_3).

2. Soil physical properties (Table 1-5)

Both the hardness and bulk density of soil increased as the soil moisture was lost after harvest of rice. (Table 1-5). As for puddling treatment, the hardness and bulk density of soil were low in non-puddling plot (P_1) as compared with those in puddled plots (P_2 and P_3). However, the effect of compost application was not observed.

3. Soil pulverization

Fig. 1-3 shows the clod size distribution of soil after each tilling. Three levels of compost application were averaged in this figure since any significant difference was not seen among the treatments.

Soil moisture content at tilling time most evidently affected the extent of soil pulverization. Tilling at high soil moisture content (M_3 plot) resulted in a low proportion of small clods. The clods smaller than 2 cm in diameter accounted for only about 20% of the whole in that plot after second tilling while such small clods were about 30% in the plots (M_1 and M_2) where moisture content was low at tilling time. In M_1 and M_2 plots, weathering of soils caused by rainfall of mid-January brought about the sharp increase of the proportion of such small clods when third tilling was made.

Puddling gave rather negative effects on soil pulverization for succeeding upland crops; the proportion of the small clods in P_1 plot was somewhat higher than those in P_2 and P_3 plots.

4. Seedling emergence in the germination test.

These was found a significant correlation between the clod size distribution in terms of the percentage of soil clods smaller than 2 cm in diameter and the emergence of maize seedlings (Fig. 1-4). This shows that well pulverized soil induces high percentage of emergence as well as rapid and uniform emergence of maize seedlings.

5. Growth of upland crops in the field.

The growth of nine upland crops was evidently inferior in M_3 plot as compared with that in M_1 and M_2 plots (Table 1-6 and 7). The extent of soil pulverization which is dependent upon soil moisture content at tilling time was obviously one of the major causes to affect the plant growth. There was not seen a significant effect of puddling and compost application on the growth of the crops.

3. Discussion

The aforementioned results clarified that well pulverized soil was prerequisite to good germination and vigorous initial growth of upland crops. However, it was also noticed that pulverization of heavy clay soils was quite difficult in practice and that hard soil clods formulated through tilling and drying could hardly be broken down without weathering by rainfall.

Soil moisture content at tilling time is the critical factor to affect the extent of soil pulverization. However, the period of time appropriate for tilling in terms of soil moisture content is rather limited since paddy fields are to be tilled in the course of drying after rice harvest.

In this connection, trials are required to introduce a higher performance of tilling attachment or develop seeding methods ensuring good germination of seeds under the existing field conditions.

Table 1-1. F Value and its significance obtained from the analysis of variance on emergence and growth of seedlings with special reference to clod size of soil

| Factor | Percentage of emergence | Rapidity of emergence | Uniformity of emergence | Plant height | Number of leaves | Dry weight | |
|------------------------------------|-------------------------|-----------------------|-------------------------|--------------|------------------|------------|-----------|
